# Introduction

This is a summary of the most important algorithms and methods in deep reinforcement learning. Work in progress.

### Multi-Armed Bandit Problem

- 2.1 Problem description
- 2.2 The epsilon-greedy policy
- 2.3 The softmax exploration algorithm
- 2.4 The upper confidence bound algorithm
- 2.5 The Thompson sampling algorithm

## Markov decision processes

#### 3.1 The agent-environment interface

The agent and environment interact at each of a sequence of discrete time steps, t = 01, 2, .... At each time step t, the agent receives some representation of the environement's state,  $S_t \in \mathcal{S}$ , and on that basis selects an action  $A_t \in \mathcal{A}(s)$ . One time step later, in part as a consequence of its action, the agent receives a numerical reward  $R_{t+1} \in \mathcal{R} \subset \mathbb{R}$ , and finds itself in a new state,  $S_{t+1}$ . The MDP and agent together thereby give rise to a sequence or trajectory that begins like this:

$$S_0, A_0, R_1, S_1, A_1, S_2, A_2, R_3, \dots$$

# Dynamic programming

# Chapter 5 Monte Carlo learning

5.1 Monte Carlo prediction

## Temporal difference learning

#### 6.1 TD prediction

Both TD and Monte Carlo methods use experience to solve the prediction problem. Given some experience following a policy  $\pi$ , both methods update their estimate V of  $v_{\pi}$  for the nonterminal states  $S_t$  occurring in that experience. Roughly speaking, Monte Carlo methods wait until the return following the visit is known, then use that return as a target for  $V(S_t)$ . A simple every-visit Monte Carlo method suitable for nonstationary environments is

$$V(S_t) \leftarrow V(S_t) + \alpha [G_t - V(S_t)], \qquad (6.1)$$

where  $G_t$  is the actual return following time t, and  $\alpha$  is a constant step-size parameter.

Whereas Monte Carlo methods must wait until the end of the episode to determine the increment to  $V(S_t)$  (only then is  $G_t$  known), TD methods need to wait only until the next step. At time t+1 they immediately form a target and make a useful update using the observed reward  $R_{t+1}$  and the estimate  $V(S_{t+1})$ . The simplest TD method makes the update

$$V(S_t) \leftarrow V(S_t) + \alpha [R_{t+1} + \gamma V(S_{t+1}) - V(S_t)]$$
(6.2)

immediately on transition to  $S_{t+1}$  and receiving  $R_{t+1}$ . In effect, the target for the Monte Carlo update is  $G_t$ , whereas the target for the TD update is  $R_{t+1} + \gamma V(S_{t+1})$ . This TD method is called TD(0), or one-step TD. It is a special case of the TD( $\lambda$ ) and n-step TD methods that described in this note as well.

#### 6.2 Sarsa: on-policy TD control

In Subsection 6.1 we considered transitions from state to state and learned the values of states. Now we consider transitions from state-action pair to state-action pair, and learn the values of state-action pairs. We use the update

$$Q(S_t, A_t) \leftarrow Q(S_t, A_t) + \alpha [R_{t+1} + \gamma Q(S_{t+1}, A_{t+1}) - Q(S_t, A_t)].$$
 (6.3)

which is done after every transition from a non-terminal state  $S_t$ . ???

#### **Algorithm 1** Tabular TD(0) for estimating $v_{\pi}$

```
Input: the policy to \pi to be evaluated Algorithm parameter: step size \alpha
Initialize V(s), for all s \in \mathcal{S}^+, arbitrarily except that V(terminal) = 0
for each episode do
Initialize S
for each step of episode do
A \leftarrow \text{action given by } \pi \text{ for } S
Take action A, observe R, S'
V(S) \leftarrow V(S) + \alpha[R + \gamma V(S') - V(S)]
S \leftarrow S'
if S is terminal then break end for end for
```

#### **Algorithm 2** Sarsa (on-policy TD control) for estimating $Q \approx q_*$

```
Initialize Q(s,a), for all s \in \mathcal{S}^+, a \in \mathcal{A}(s), arbitrarily except that Q(terminal,\cdot) = 0 for each episode do

Initialize S
Choose A from S using policy derived from Q (e.g., \epsilon-greedy)

for each step of episode do

Take action A, observe R, S'
Choose A' from S' using policy derived from Q (e.g., \epsilon-greedy)

Q(S,A) \leftarrow Q(S,A) + \alpha[R + \gamma Q(S',A') - Q(S,A)]
S \leftarrow S'; A \leftarrow A';

if S is terminal then break

end for
```

#### 6.3 Expected Sarsa

Consider the learning algorithm that is just like Q-learning except that instead of the maximum over next state-action pairs it uses the expected value, taking into account how likely each action is under the current policy. That is, consider the algorithm with the update rule

$$Q(S_{t}, A_{t}) \leftarrow Q(S_{t}, A_{t}) + \alpha \left[ R_{t+1} + \gamma \mathbb{E}_{\pi} [Q(S_{t+1}, A_{t+1}) | S_{t+1}] - Q(S_{t}, A_{t}) \right]$$

$$\leftarrow Q(S_{t}, A_{t}) + \alpha \left[ R_{t+1} + \gamma \sum_{a} \pi(a | S_{t+1}) Q(S_{t+1}, a) - Q(S_{t}, A_{t}) \right],$$

but that otherwise follows the schema of Q-learning.

#### 6.4 Q-learning: off-policy TD control

One of this early breakthroughs in reinforcement learning was the development of an offpolicy TD control algorithm known as Q-learning, defined by

$$Q(S_t, A_t) \leftarrow Q(S_t, A_t) + \alpha [R_{t+1} + \gamma \max_{a} Q(S_{t+1}, a) - Q(S_t, A_t)].$$
 (6.4)

In this case, the learned action-value function, Q, directly approximates  $q_*$ , the optimal action-value function, independent of the policy being followed. The policy still has an effect in that it determines which state-action pairs are visited an updated. However, all that is required for the correct convergence is that all pairs continue to be updated.

```
Algorithm 3 Q-learning (off-policy TD control) for estimating \pi \approx \pi_*

Algorithm parameters: step size \alpha \in (0,1], small \epsilon > 0

Initialize Q(s,a), for all s \in \mathcal{S}^+, a \in \mathcal{A}(s), except that Q(terminal, \cdot) = 0

for each episode do

Initialize S

for each step of the episode do

Choose A from S using policy derived from Q (e.g., \epsilon-greedy)

Take action A, observe R, S'

Q(S,A) \leftarrow Q(S,A) + \alpha[R + \gamma \max_a Q(S',a) - Q(S,A)]
S \leftarrow S'

if S is terminal then break

end for

end for
```

#### 6.5 Double Q-learning

All previously discussed control algorithms involve maximization in the construction of their target policies. In these algorithms, a maximum over estimated values is used implicitly as an estimate of the maximum value, which can lead to a significant positive bias. To see why, consider a single state s where there are many actions a whose true values q(s,a), are all zero but whose estimated values Q(s,a), are uncertain and thus distributed some above and some below zero. The maximum of these values is zero, but the maximum of the estimates is positive, a positive bias. We call this maximization bias.

```
Algorithm 4 Double Q-learning, for estimating Q_1 \approx Q_2 \approx q_*

Algorithm parameters: step size \alpha \in (0,1], small \epsilon > 0

Initialize Q_1(s,a) and Q_2(s,a), for all s \in \mathcal{S}^+, a \in \mathcal{A}(s), such that Q(terminal,\cdot) = 0

for each episode do

Initialize S

for each step of episode do

Choose A from S using the policy \epsilon-greedy in Q_1 + Q_2

Take action A, observe R, S'

With probability 0.5

Q_1(S,A) \leftarrow Q_1(S,A) + \alpha[R + \gamma Q_2(S', \operatorname{argmax}_a Q_1(S',a)) - Q_1(S,A)]

else

Q_2(S,A) \leftarrow Q_2(S,A) + \alpha[R + \gamma Q_1(S', \operatorname{argmax}_a Q_2(S',a)) - Q_2(S,A)]
S \leftarrow S'

if S terminal then break

end for
end for
```
